Thirty-Second Report of the International Whaling Commission

Covering the thirty-second financial year 1980–1981
Approved by the Commission at its thirty-third meeting in Brighton, June 1981
Authorised to be printed together with the Chairman's Report of the thirty-third meeting.

Cambridge
1982

The International Whaling Commission
was constituted under the International Convention for the
Regulation of Whaling signed at Washington on 2 December 1946.

The International Whaling Commission

The Red House, Station Road, Histon,
Cambridge CB4 4NP

Preface

This year's Annual Report contains materials from the following meetings:
the 33rd Annual Commission and Scientific Committee Meetings;
the Workshop on the Design of Sightings Surveys;
the Workshop on the Identity, Structure and Vital Rates of Killer Whale Populations: and
the Special Meeting on Southern Hemisphere Minke Whales.

In addition to the Reports of these meetings, eighty-seven scientific papers are included, all of which have been revised to some extent since their presentation to the Scientific Committee. Copies of papers presented to the Scientific Committee but not published here can be obtained from the Office of the Commission at cost price.

GREG DONOVAN
Scientific Editor

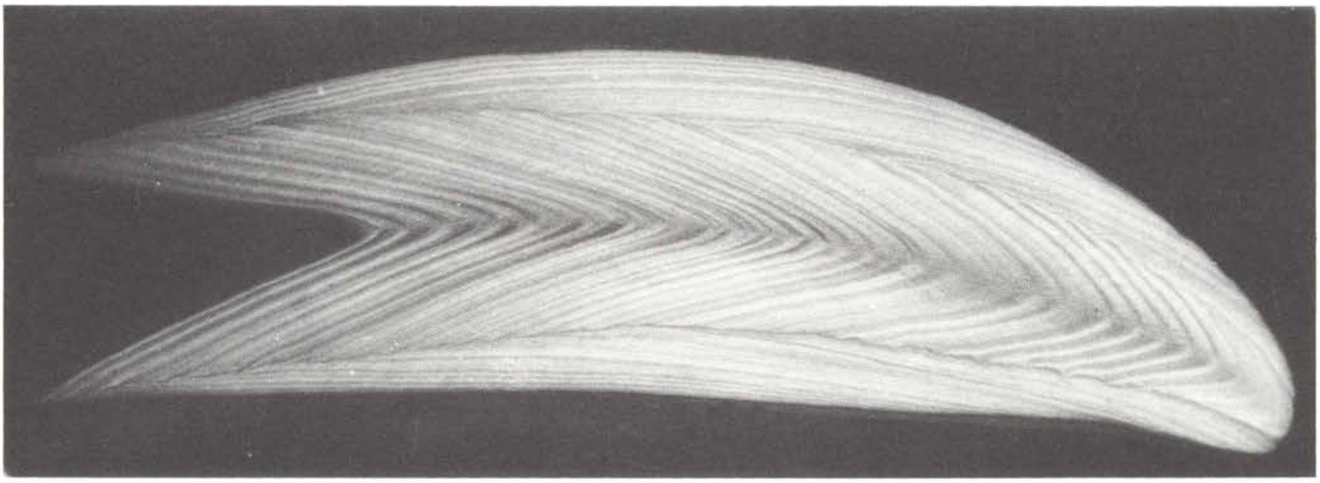

Fig. 1. Decalcified cut surface of a male sperm-whale tooth.

Expert or subjective assessment of laminations

The age of sperm whales is arrived at by the estimation of the number of main layers or GLGs. This approach has enabled general conclusions to be drawn on the life-span of sperm whales, the growth curves of males and females, the ages at sexual and physical maturity, and to allow determination of the correlation between different age groups etc.

However, at the same time, the complex nature of the laminations and the problems associated with determining additional from main layers does not always allow us to estimate the number of annual layers with 'absolute' accuracy as it is now understood. For these reasons, the age determination of sperm whales is often 'erroneous' and is to some extent subjective. It often happens that investigators in the same laboratory using the same methods and with the same scientific opinions arrive at different assessments of the GLG number; the differences are not great but do exist. Indeed the very fact that 'experts' are used emphasises the subjective nature of aging teeth: there is no need for 'experts' when the investigated characteristics are obvious and discrete, e.g. when determining the number of ventral grooves. Strictly speaking, expert assessments are qualitative and not therefore an 'assessment'. Although numbers may be used in expert assessments they are only rough, approximate and subjective. For example, in assessing mastery in certain sports (e.g. figure skating, gymnastics etc.) the experts can arrange the sportsmen in order of merit easily enough but cannot give a true quantitative assessment of the degree of mastery of one sportsman over another. Although this is an extreme example, an increase in the number of experts cannot practically alter this and the essence of the assessment will remain qualitative and subjective. One question which may well be asked is whether an expert assessment can in general be a scientific one?

Turin (1978), in examining certain nonparametric statistical methods wrote: 'expert assessment has been popular in certain circles. Some specialists are ready to use experts in any difficult case. Others consider the value of using experts to be fictional and believe that such methods will soon be out of fashion'. I believe that such an approach is valid only up until quantitative and objective assessment methods have been developed. One of the peculiarities of expert assessment is that increasing the number of experts serves only to increase the variation and that therefore there is no reason their number should exceed 5–6 persons. It should also be remembered that both the mean and extreme values have a similar probability of coinciding with (or indeed differing from) the true value. The results of each expert may be more 'truthful' than the total averaged solution. This was confirmed in the results of Donovan *et al.* (1982) where there was clear variation in the readings.

I do not believe that it is correct to average the results obtained by different experts as there are no grounds to suppose that average values are closer to the 'true' values. Averaging also tends to hide the divergences in the results of the experts. Fig. 2 shows that the divergences seen in the GLG counts between the first and second experts are practically the same as those between the second and third experts, i.e. between two English experts. In the first case, the readings coincide in 5 cases, and are higher for the first reader on 29 occasions and lower on 16 occasions. In the second case, readings coincide 7 times, and are higher for the second expert on 27 occasions and lower on 16.

To assess the significance of these divergences I have used a range Willcockson method used for the variants conjugated by two (Urbah, 1963), as possessing a great effect. The 'U-criterion' appeared to be 2.17 in the first case and 2.16 in the second one. That is the truthfulness of the assessment divergences between the first and second experts and the second and third ones is almost the same, within the ranges of 0.05 and 0.01 levels of significance.

It is clear that averaging could be applied not only for the four experts, but also with all six, and that the results would be very close (although not necessarily closer to the truth).

To illustrate the subjectivity in GLG counts, the results of the second, third, fourth and sixth experts coincided on only three out of 50 comparisons performed and on only 11 occasions did the values obtained by three out of four readers coincide. In all other cases the readings, although close, were different.

I have noted that increasing the number of experts only increases the variation. To obtain the base material for this paper, the same 50 teeth were sent to Dr A. A. Berzin (TINRO, Vladivostok) and Dr G. A. Klevezal (Institute of the Biology of Animal Development, USSR Academy of Sciences, Moscow). Their results are given in Table 1.

The readings given by Dr Berzin (the seventh expert) are between those given by the first and second experts, and those of Dr Klevezal (the eighth expert) are between the

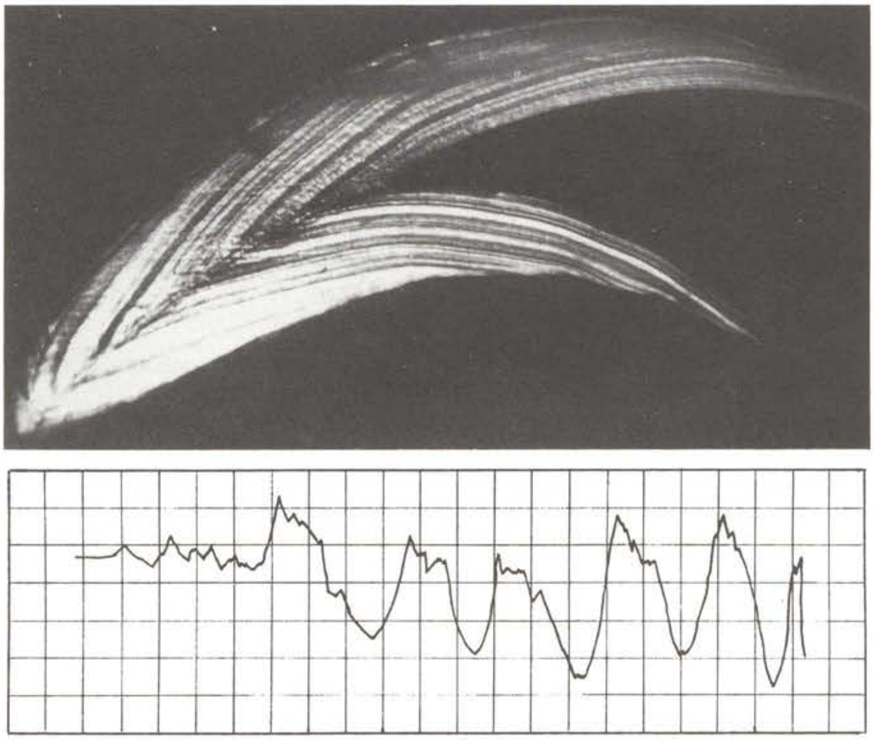

Fig. 3. Decalcified cut surface of a tooth of a young female sperm whale (above) and a profilogram of this tooth (below).

we have seen earlier, these layers were termed 'marks' by Klevezal and Tormosov (1971). The distances between layers are not always constant which does not allow accurate estimation of GLGs in difficult areas.

However, if the layering is not clear to the naked eye, it may become more clear if a profilogram of the surface relief of the tooth is made (Fig. 5). Methods for obtaining profilograms and microphotograms were described some years ago (Mikhalev, 1975a and b; 1977). They are almost the same as the methods used to obtain profilograms (Utrecht-Cock, van, 1965) and photograms (Ichihara, 1963) for the 'registering structures' (baleen plates, ear plugs) of baleen whales. Profilograms reveal the undulating character of the laminations even when the layers are distinctively observed. (Fig. 3).

This undulating nature is interesting and may lead to a further line of investigation. Mikhalev (1975a) postulated the possibility of a relationship between the character of the laminations and solar activity, as has been observed in trees. This possibility can and should be further examined by considering photographs and profilograms of cut teeth (Figs 1, 4 and 5). If such a connection is confirmed, this will help to answer the problem of how many and what kind of layers are formed throughout a year.

Although obtaining profilograms and microphotograms is very time consuming it does open the possibility of

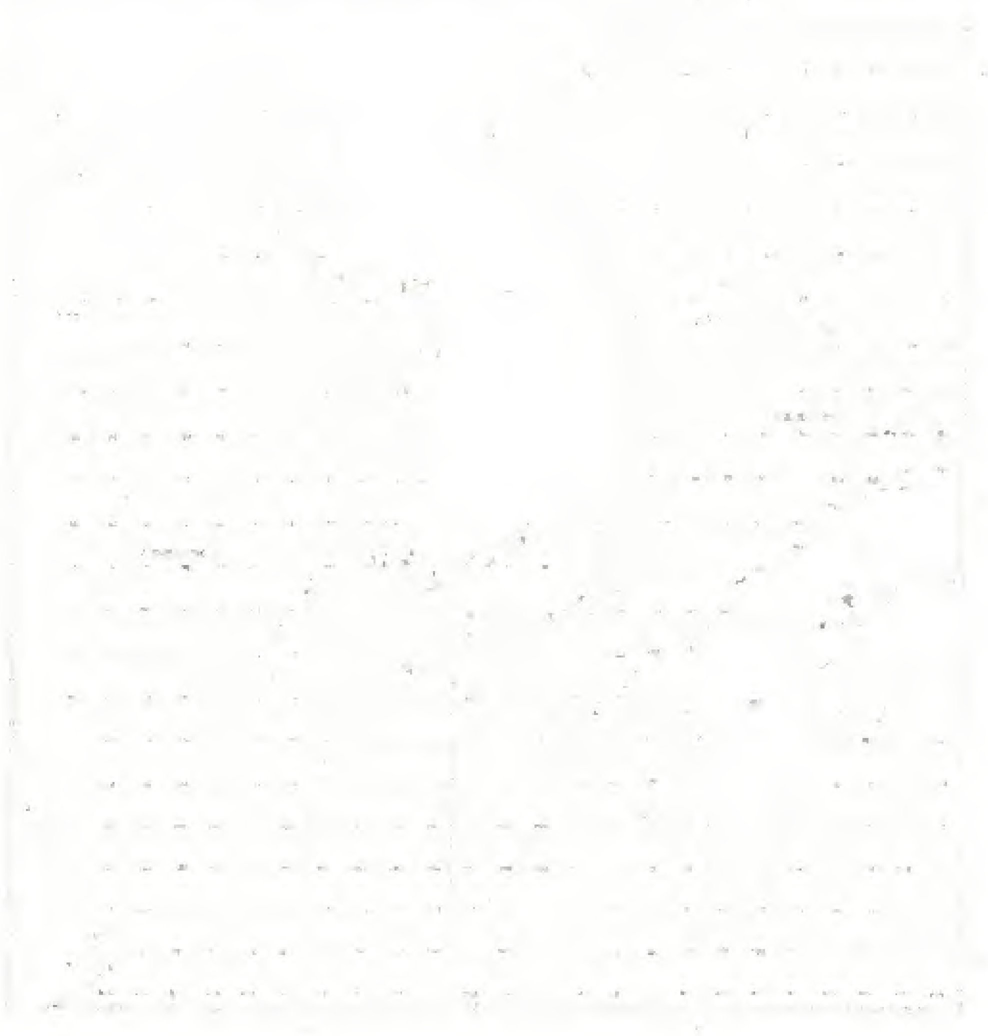

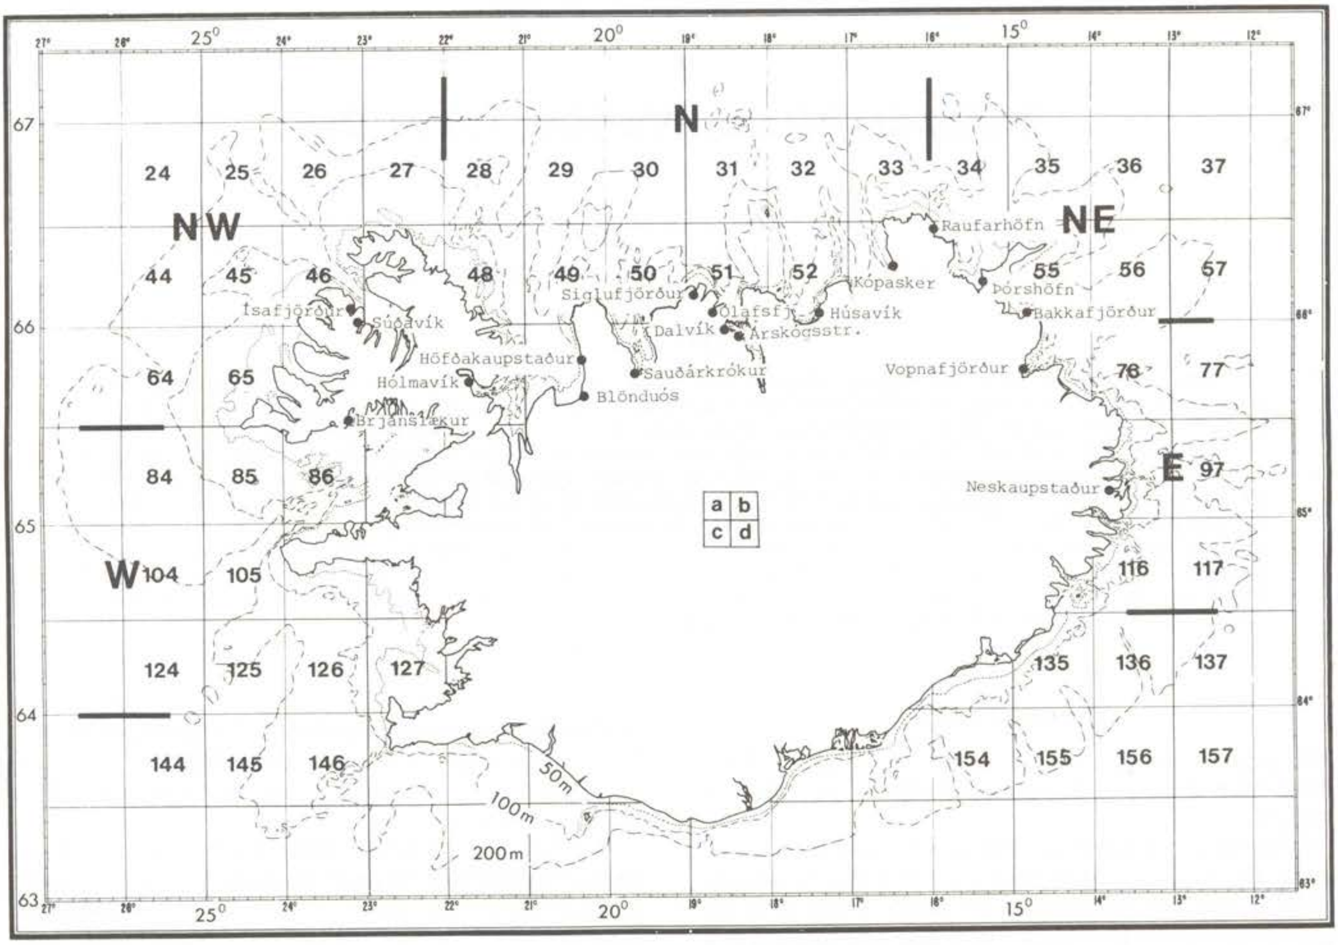

Fig. 1. Towns in Iceland where minke whales are frequently landed, statistical divisions of the whaling grounds and division of the grounds into operation areas (W, NW, N, NE, E).

Today all the minke whalers are also engaged in fishing activities outside the minke whale season. The fish species caught include cod (*Gadus morhua*), lumpsucker (*Cyclopterus lumpus*) and shrimp (*Pandalus borealis*). The catchers are therefore equipped with several instruments which are standard on small fishing vessels, such as far and short ranging radio telephone systems, echo sounders and radar, while in recent years some boats also have automatic direction finders and the loran navigation system.

PROCESSING AND DISTRIBUTION OF PRODUCTS

Meat has always been the most important product from minke whales in the coastal areas of Iceland, where human consumption of minke whale meat has a long tradition. In the past it was a most welcome addition to the poor variability of food items available to the people. The whales were fully utilized. Not only the meat itself was eaten but also the flukes, flippers, tongue, blubber and ventral grooves. In the past most of the products were eaten fresh or salted, although sometimes smoked or soured. The blubber was often boiled to extract the oil.

Although some catchers are now able to work up small animals on board at sea, this is usually considered too risky. Generally the whales are towed to the nearest town for flensing and cooling of the meat as was the practice in the past. As shown in Fig. 1 the landings are restricted to towns spreading clockwise from W- to E-Iceland.

Two landing places can be considered as land stations. The land station in Brjánslaekur, W-Iceland serves two vessels, while the Árskógsströnd station serves one catcher (see Fig. 1). A slipway has been constructed and a modern freezing plant (used also for fish products) is available.

Government ordinances

The recent governmental ordinances concerning Icelandic minke whaling are based on the IWC regulatory items. The main articles for the 1981 season were:

1. *Catch quota:* The total quota is 200 minke whales for the season. Each boat is allowed to take a fixed number of whales.
2. *Catch limits:* Only minke whales are allowed to be taken. Calves, and cows with calves are protected.
3. *Season:* The licences are issued for the period 20 May–1 September, but will be reviewed if less than 200 whales are caught by 1 September.
4. *Catch area:* Catches are only allowed to be taken within the 200 nautical miles Icelandic fisheries jurisdiction.
5. *Catch equipment:* Harpoon guns used for killing the whales have to be authorized by the Ministry of Fisheries.
6. *Handling:* After the whale is killed it has to be handled in the particular way outlined to ensure full utilization of the products. The whale should be landed within 18 hours of death.
7. *Scientific cooperation:* Cooperation with inspectors from the Ministry of Fisheries or scientific personnel from the Marine Research Institute is required.

Fig. 4. Kongsberg 50 mm harpoon gun mounted on the bow of *Sólrún EA 151*.

8. *Catch records:* Twice a month a catch record is to be filled out and sent to the Marine Research Institute, Reykjavík. The catch records shall include name of the catcher boat, name of gunner, date and position of whales caught (statistical divisions shown on Fig. 1), sex, body length, length and sex of foetus and other information on whales caught, such as food.
9. Any violation of the regulations listed above will be met with a punishment or fines according to Icelandic legislation.

The Ministry of Fisheries has no special arrangement to ensure that all of the articles are upheld. For economic reasons it would be very difficult to send an inspector on board every vessel since whaling operations are spread in both time and area. However, the Ministry sends inspectors to most of the fishing towns where minke whales are landed to control the fisheries and these inspectors are also instructed to keep an eye on minke whaling.

DEVELOPMENT OF THE WHALING

In his description of whales in Icelandic waters in the 18th century, Ólafsson (1772) writes that minke whales are seldom harpooned because the local people considered the minke whale a 'good' whale sent by God to defend the people and their boats against 'bad' species of whales. According to Saemundsson (1932) minke whales were not caught in Iceland until 1914 although a few animals may have been killed during whaling experiments in NW-Iceland and Eyjafjördur (N-Iceland) during the 17th century.

Icelandic catches in the period 1914–80

Table 1 gives all known information on catches taken by Icelandic whalers since 1914. The number of whales taken has been based on many different sources of information, as discussed below.

Saemundsson (1931; 1937) gave information on minke whales caught between 1914 and 1936 in NW- and N-Iceland. Saemundsson's catch records seem to be complete for NW-Iceland for that period since he received records of whales taken by *Margrét ÍS 314* which (according to local people) was the only catcher operating in that area. For N-Iceland, Saemundsson only reported the number of whales caught (see 'Various boats' in Table 1), without referring to any particular vessel. Information from local people indicates a somewhat higher total catch in N-Icelandic coastal waters than that given by Saemundsson (1931; 1937) for the period 1920–35, when according to local information no less than nine vessels were to some extent involved in whaling. The catches under 'Various boats' in Table 1 should therefore be regarded as minimum values.

Saemundsson (1931; 1937) did not mention minke whaling in any other coastal areas around Iceland. However, to my knowledge (local information) at least one vessel was operating in the coastal waters off E-Iceland in the 1920s. In 1923 fishermen in E-Iceland argued for a cessation of minke whaling inside the fjords, since it 'caused serious harm to the herring fisheries' (Anon., 1924). This proves that minke whaling already existed in this area, but no estimates of the number of whales taken can be made.

For the period 1937–73 no official catch data are available. Information on catches in this period is either based on private catch records made by the gunners or on my personal interviews with them. In this way an estimate of their catches through the years has been established. I attempted to avoid overestimating the catches, and therefore the figures in Table 1 are conservative. Since 1974 regular catch records have been received from minke whalers giving the true number of whales caught in the period 1974–80.

From Table 1, a minimum of 3,362 minke whales were killed in the period 1914–80. Fig. 5 shows the average (in 1914 only one whale was taken and in 1915 ten animals) annual catch for each five year period between 1916–80. It must be remembered that the data might be incomplete for the greater part of the period and in particular for the early years. However, it is evident that the number of whales taken has increased in the post-war years, especially in the 1960s and 1970s. The average annual catches for 1966–70, 1971–75 and 1976–80 were 105, 137 and 200, respectively.

Table 2

Number of licences issued to minke whalers in Iceland 1975–80 and number of catchers taking more than 10 whales each year

Year	No. of licences issued	No. of vessels participating	No. of boats taking more than 10 whales
1975[1]	6	9	4
1976	12	11	5
1977	14	10	6
1978	10	10	7
1979	11	10	5
1980	11	8	7

[1] In 1975 10 whales were caught by three unlicensed vessels.

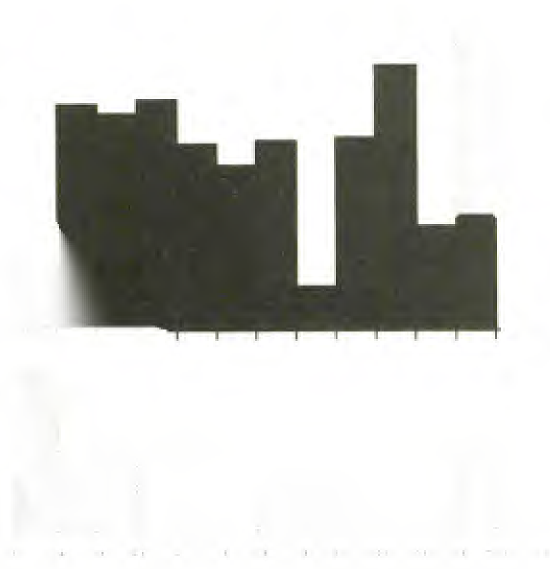

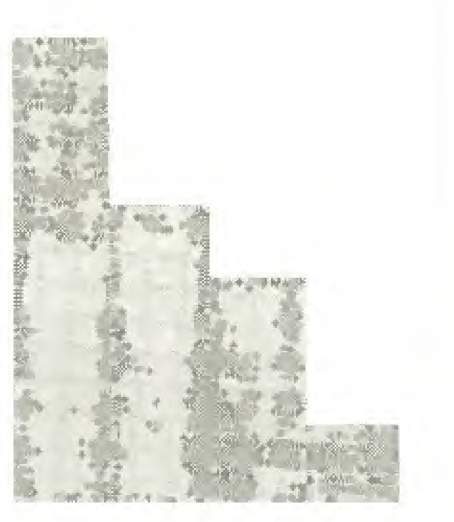

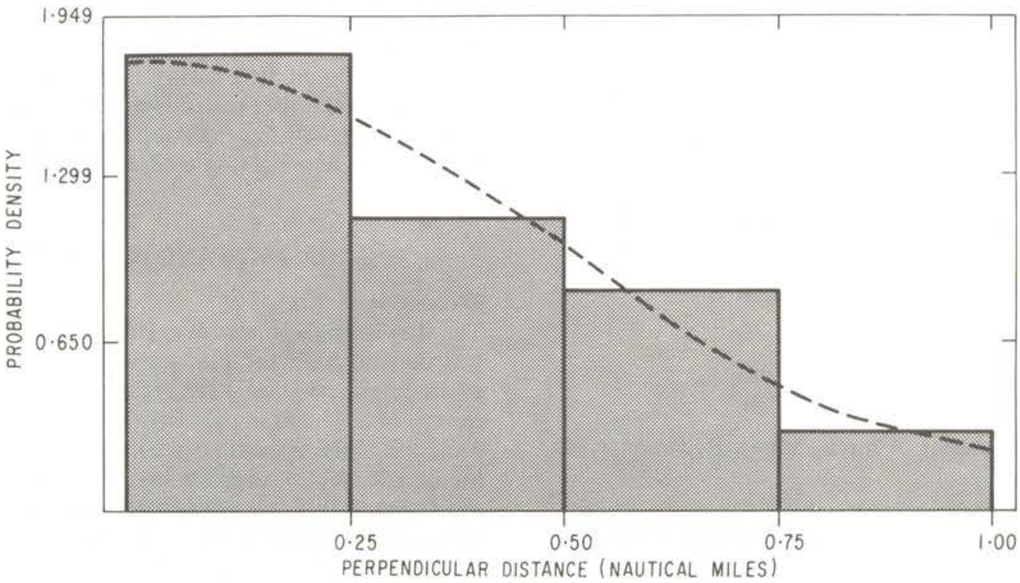

Fig. 4. The Fourier series estimator of the probability density function of perpendicular distances (dashed line) fit to the histogram of the data for all primary large whale sightings.

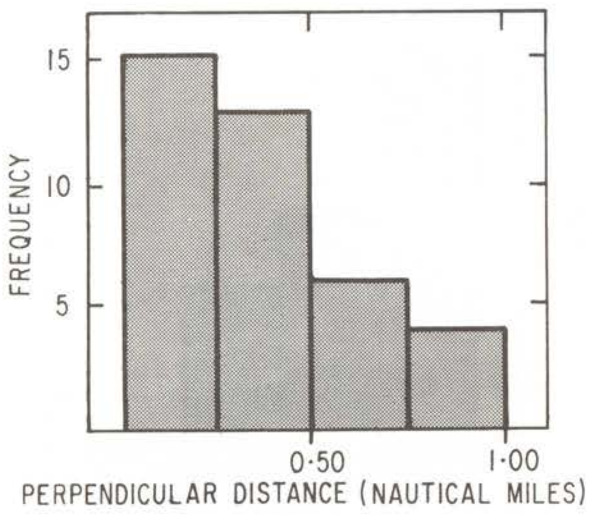

Fig. 5. Frequency distribution of right-angle distances, primary pilot whale sightings.

Group size

The mean pod sizes (considering primary sightings only) with their standard errors for each species are presented in Table 2. Although it is intuitively obvious that sighting probability should be a function of pod size, differential sightability of different pod sizes does not present problems for the estimation of pod density. Quinn (1979) has demonstrated, by computer simulation, that several

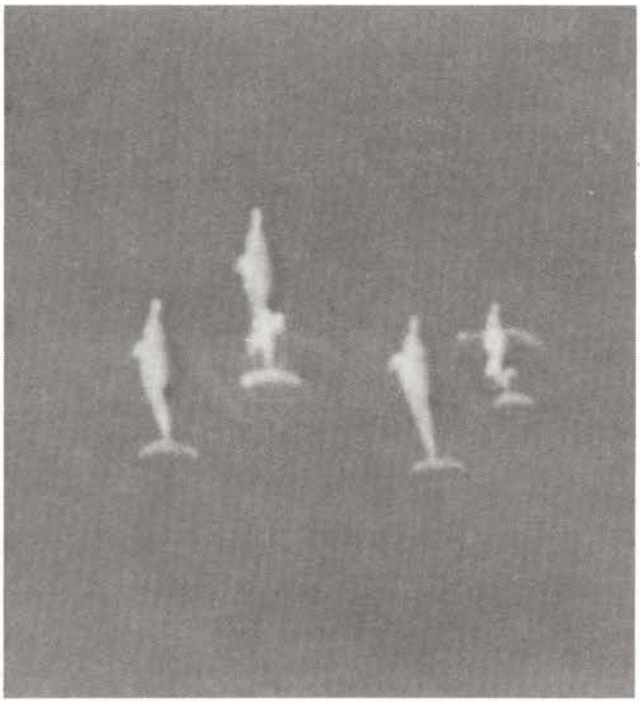

Fig. 6. Four unidentified medium-sized whales, believed to be beaked whales, *Mesoplodon sp.*, including a calf, observed 27 April 1980 at lat. 04°03.1′S, long. 56°70′E. They were tentatively identified as *M. grayi* or *M. pacificus* (= *Indopacetus pacificus*).

Other information

Best (1971) reported that killer whales occur in the Seychelles. On 16 August 1980 David Plows and Francois Jackson (October 1980 pers. comm.) observed three whales at 06°06′S, 57°36′E. From their detailed descriptions the whales were unquestionably killer whales.

Seven species of cetaceans previously reported to occur in the Seychelles were not observed during the present survey (Table 2). A whale, identified as a right whale, *Balaena glacialis* (cited as *Baleine franche* or *Baloena australi*), was included in the take of the fishery for sperm whales near Bird and Denis Islands discussed above[2]. At least twelve pygmy killer whales, *Feresa attenuata,* were reportedly observed in May of 1977, west of Seychelles Bank; and nine small whales stranded on Aldabra in spring of 1975 were later identified from skulls as melon-headed whales, *Peponocephala electra* (Racey and Nicoll, in press).

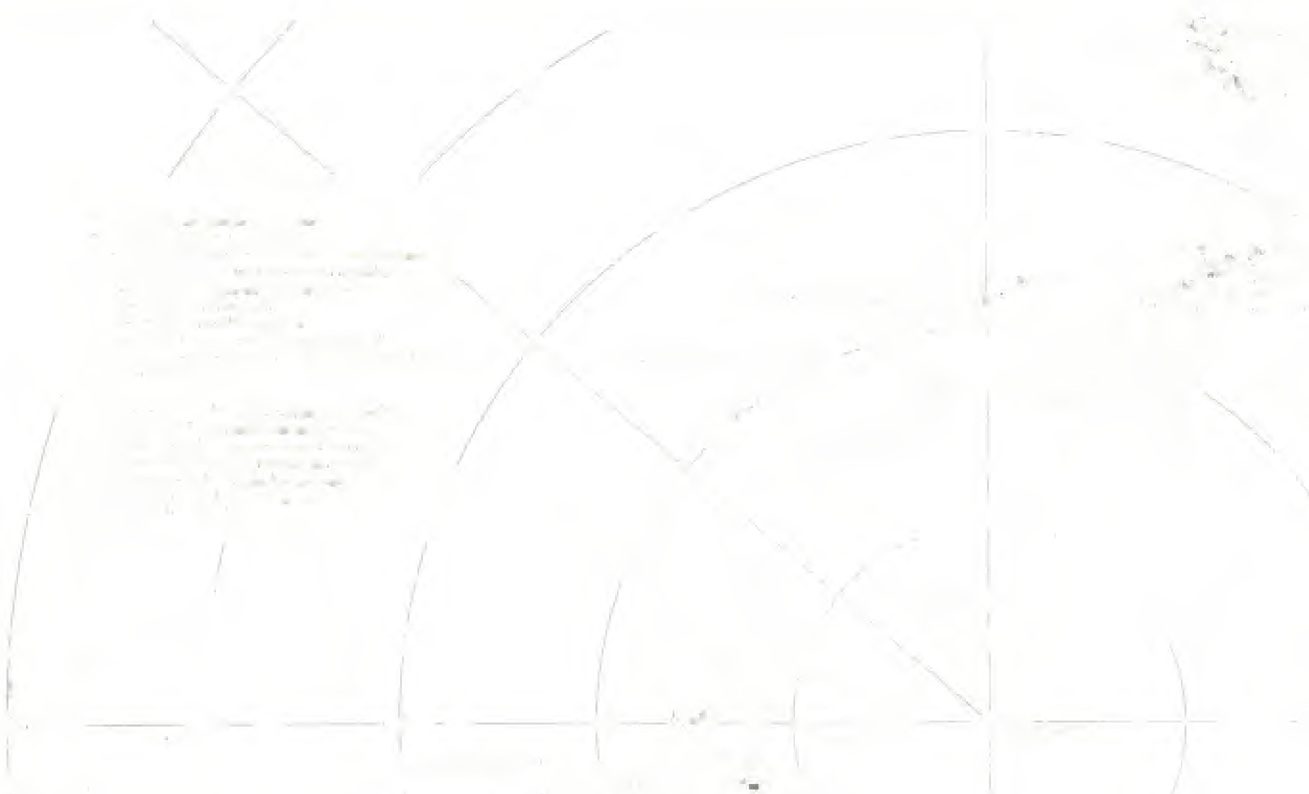
Sei whales are regarded as 'probably [occurring] throughout Indian . . . Ocean' (Best, 1971) and were thought by Seychelles authorities in 1915 to migrate seasonally into the area and therefore likely to be harpooned in the fishery. Blue and minke whales have been seen in the Gulf of Aden (Yukhov, 1969) and in temperate waters well south of Madagascar (Gambell *et al.*, 1975). Minke whales were observed as far north as about 21°S off both coasts of Madagascar and eastwards towards Mauritius (Gambell *et al.*, 1975). Humpback whales were killed off Mozambique and Madagascar by yankee whalers in the 19th century (Townsend, 1935) and off Mozambique by modern whaling from 1911–1915 and in 1923 (Rørvik, 1979).

[2] No substantive evidence supporting the identification of this specimen as a right whale was presented. Because of the much reduced stocks of right whales and oceanic nature of the islands the identification must be regarded with caution (G. J. B. Ross, 1981, pers. comm.).

ACKNOWLEDGEMENTS

The results reported in the paper were generously supported by the International Fund for Animal Welfare. The authors thank the organization, particularly Mr Brian Davis, for their support and generosity. The authors also thank the following institutions and individuals for assistance with this project: President Rene and the Seychelles government, particularly the Minister of Agriculture, Karl St Ange, and Serge Savy and Roger Wilson; Kantilal Jevan Shah and Lyall Watson for their support and use of their equipment; James McDevitt, pilot, for his skill and patience; Norman Van Swelm, photographer, for his excellent photographs and tireless participation in all phases of the project's field phase; and Ronn Storro-Patterson for his assistance with design of the surveys. For the summary of previous records of cetaceans in Seychelles we depended heavily on an as yet unpublished manuscript by P. A. Racey and M. E. Nicoll, generously shared with the senior author. Leatherwood was supported by Hubbs Sea World Research Insitute. This manuscript incorporates review comments by Drs P. A. Racey, G. J. B. Ross and W. F. Perrin. Annellen Sacco typed the manuscript, Chick Hayashi prepared the illustrations.

Fig. 7. Lateral view of the skull of a goosebeaked whale (*Ziphius cavirostris*) stranded on Bird Island, March 1977.



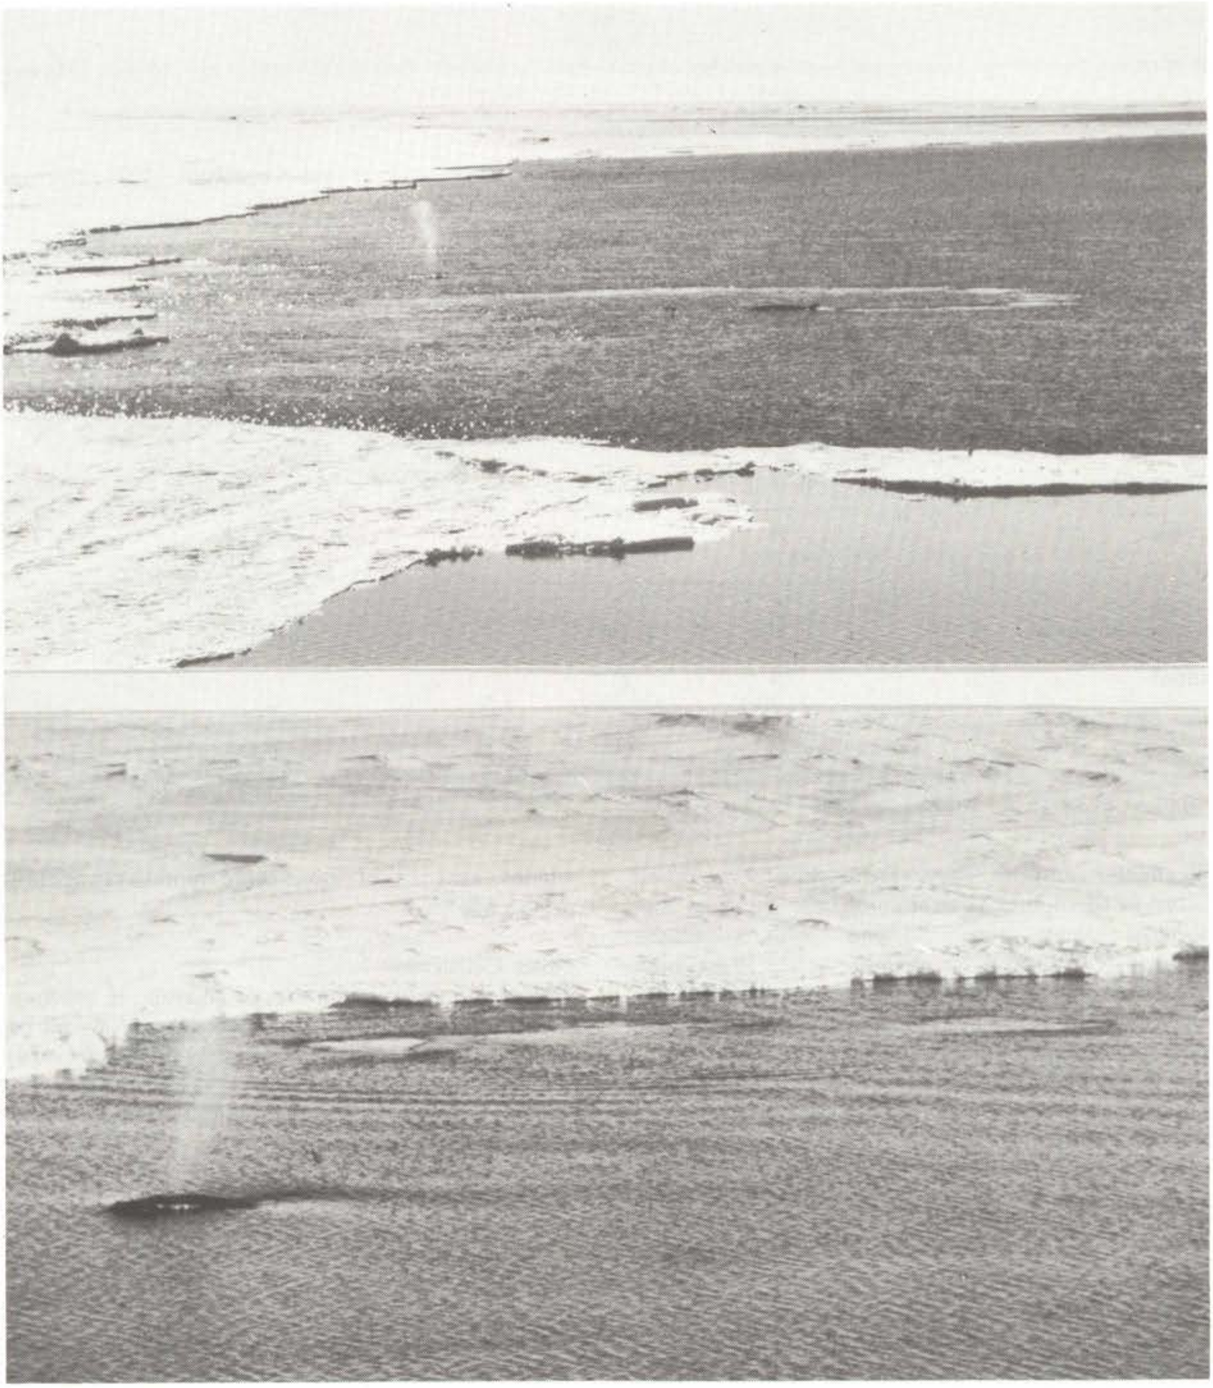


Fig. 2. Minke whales near the fast-ice edge in the southwestern Ross Sea. Note the arrangement of the slicks, parallel to the ice edge (bottom) and semicircular (top). This second pattern was a typical record of whales emerging from under the ice into open water and briefly hyperventilating before resubmerging under the ice.

was travelling at 11–12 kts (20.3–22.2 km/m). When reaching burst speeds, the whales half-breached, clearly presenting features at the cape, head, beak and body proportions sufficient for identification.

Arnoux's beaked whales, *Berardius arnuxii*, were encountered on two occasions, a pair in water 32°F (0°C) and 1,988 fathoms (3,636 m) and an individual in water 39°F (3.9°C) and 1,959 fathoms (3,583). Identification was facilitated by the animals' propensity for surfacing at angles steep to water surface, exposing much of the beak, head and upper body nearly to the flippers, and by the small, sub-triangular dorsal fin. This species has not been previously reported from Area VI (Brownell, 1974).

Of the four instances in which medium sized whales encountered could not be positively identified, two groups were most likely pilot whales and one individual was tentatively identified as a beaked whale.

Dolphins/Porpoises

We encountered an estimated 0.135 herds and 1.480 individuals of dolphins, and, possibly, porpoises per 100 nm (185 km) (Table 5). Five species were positively identified. Of the 25 herds and 275 individuals encountered, 13 herds and 140 individuals were members of the genus *Lagenorhynchus*.

animal or group. Secondly, it has been shown that a positive bias can be introduced into density estimates if the target is moving at a significant velocity relative to that of the surveying vehicle (Koopman, 1956). Thirdly, the potential mobility of the animals means that if they should react to the approach of the surveying vehicle a further bias might be introduced into density estimates. Such a reaction could be positive or negative, producing a respective over- or under-estimation of density. While it might be thought that a negative reaction would be more likely, positive 'ship-seeking' behaviour has been postulated for at least one species of *Balaenoptera* (Mitchell, 1978), although field data do not necessarily support this contention (Best and Butterworth, 1980; Horwood, 1981).[2] Ship-avoidance or ship-seeking behaviour could also have considerable bearing on the type of detection function to be used (Horwood, 1981). Lastly, the mobility of the animals confounds the difficulties of obtaining accurate sighting distance measurements if the time lapsed × speed method is used to calculate distance.

5. Gregariousness

Most whales are gregarious animals, so that the sighting of one animal is not necessarily independent of the sighting of another ('clustered objects'). Although this may not cause any problem in terms of estimation of the number of schools, if the probability of detection is related to the size of the school then the sample of school sizes obtained by line transect sampling will be biassed towards larger schools, thus creating a bias in estimation of total whale numbers. Because larger schools presumably produce more cues (blows, jumps, etc) per unit time than smaller schools, a greater probability of detecting larger schools of minke whales has been identified, and attempts have been made to account for this bias in estimating the total population size (Best and Butterworth, 1980; Chapman, 1980; Horwood, 1981).

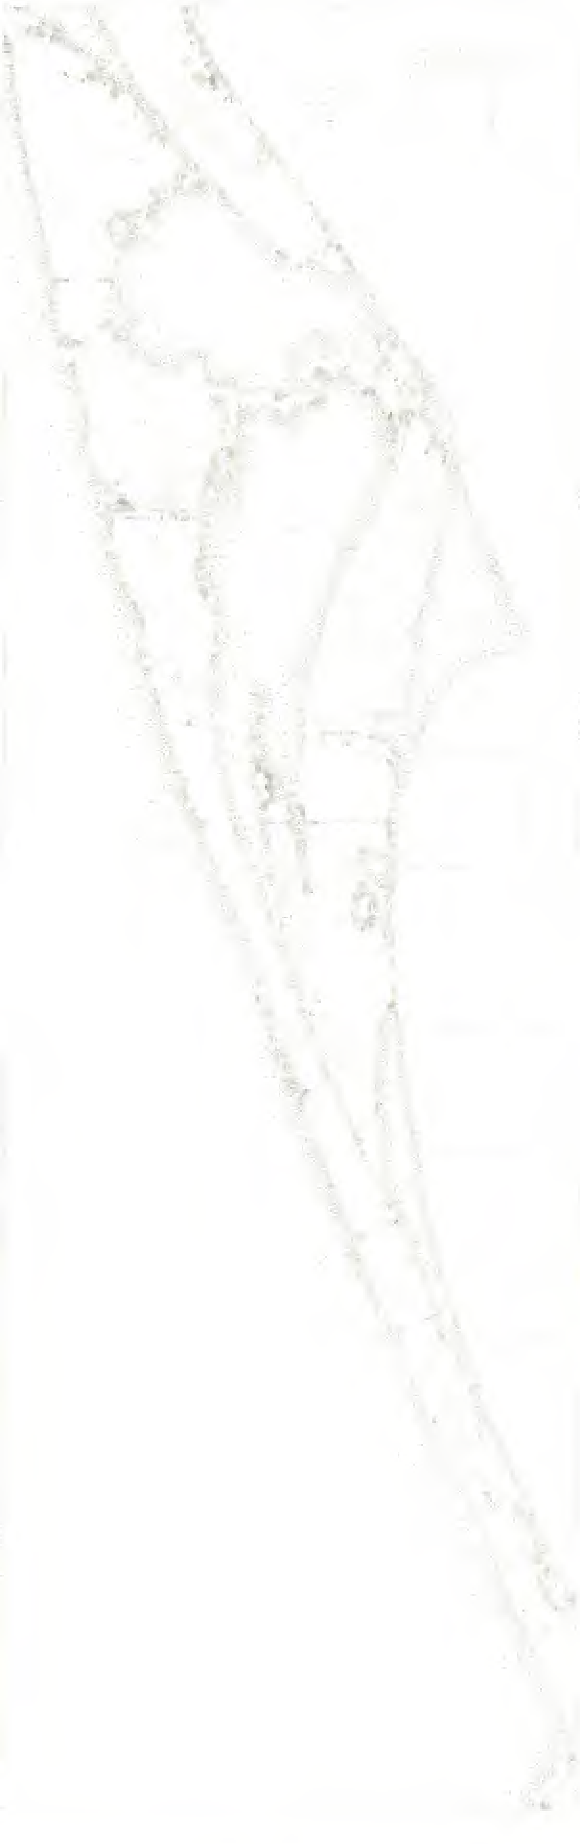
CONCLUSIONS

Certain characteristics of the biology of whales do not make them ideal subjects for the use of line transect theory to estimate density or population size. Burnham *et al.* (1980) list four assumptions that they consider critical to the achievement of reliable estimates from line transect sampling, given in order of importance below.

1. Objects directly on the line will never be missed.
2. Objects are fixed at the initial sighting position; they do not move before being detected and none are counted twice.
3. Distances and angles are measured exactly; thus, neither measurement errors nor rounding errors occur.
4. Sightings are independent events.

Clearly there are problems in satisfying the first three assumptions in the case of surveys for whales. In view of the discussions to be held at this meeting, however, it would be premature to conclude that these difficulties preclude the use of line transect sampling as one method of population estimation for these species. The likely direction (if not the possible extent) of some of the biases in such estimates could be identified and subsequently taken into account in the setting of appropriate management regimes.

[2] Results of experiments concerned with ship-seeking behaviour, which were carried out as a result of the meeting to which this paper was presented are given in Leatherwood *et al.* (1982) and Butterworth, Best and Basson (1982).



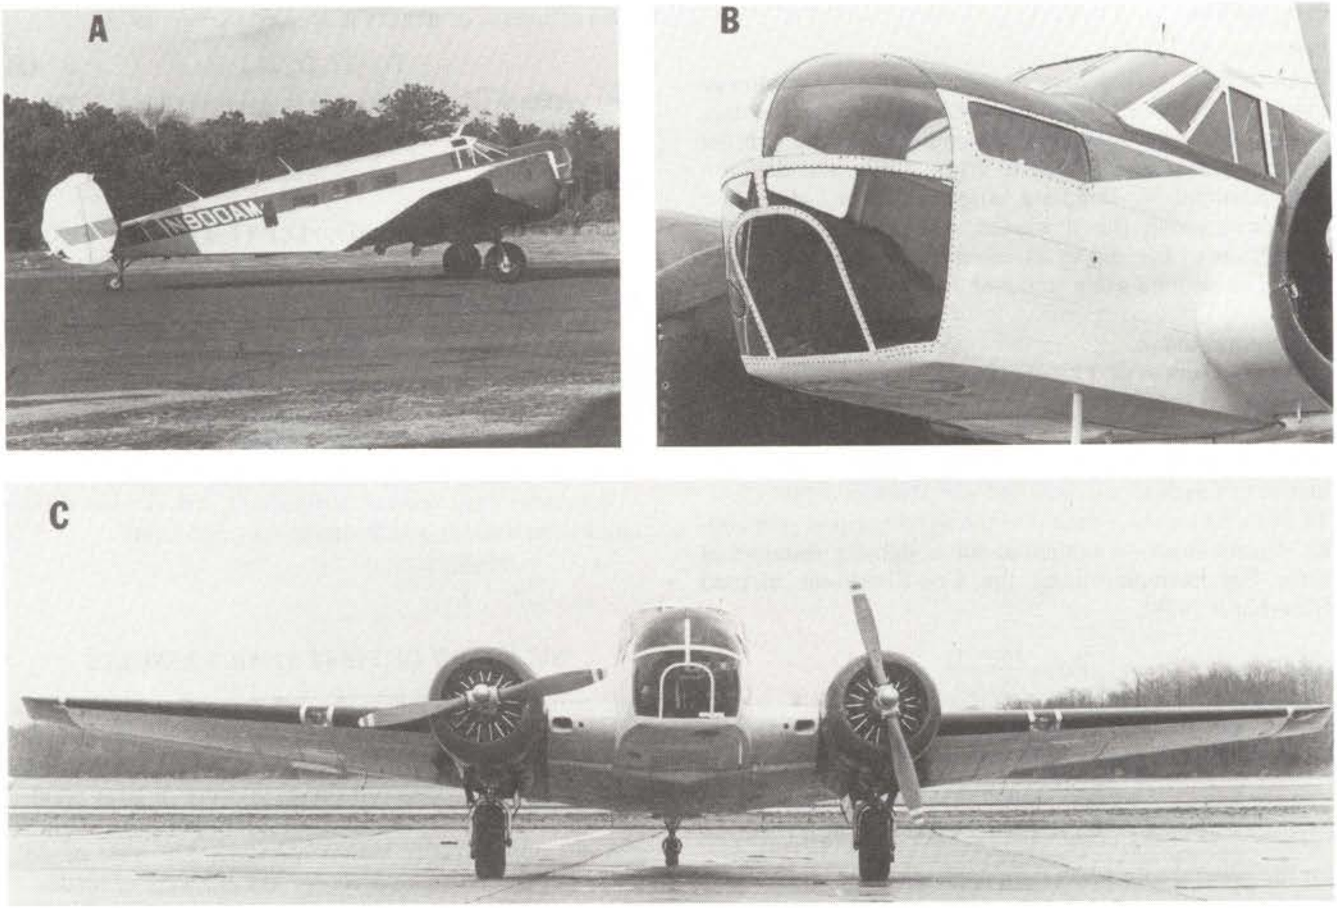


Fig. 3. The Beechcraft AT-11 survey plane. Plates A and C present the front and side aspects of the plane. Plate B is a close-up of the forward blister in which two observers are stationed.

cruising speeds of between 200 and 240 km/hr when in the CETAP configuration (six passengers).

Survey techniques

Survey teams consist of six persons including the pilot, a co-pilot/navigator and four observers. Observers are randomly paired and placed in the forward blister while on transect. Each observer scans the water surface from the bow to approximately 60° port or starboard. A full 90° scan is not possible due to the confined space in the observation blister. The blister observers are responsible for reporting sightings of cetaceans, turtles and other biological data (including human activities) in his(her) field of view over the intercom system to the data recorder. Additional data such as Beaufort sea state, amount and position of glare in the field of view, visibility and cloud cover are also reported and recorded at the beginning of each transect and as these conditions change. Observers are rotated from the blister at the end of each transect or after one hour on watch, whichever occurs first. The off-duty observers alternate off-watch periods at the data recorder station and the rest position. In addition to hand-written notes, voice notes are recorded on magnetic tape through the intercom system.

The navigator is responsible for recording the aircraft position at five minute intervals as well as marking the radiometer strip chart at the same time. Position and temperature information is also recorded upon each sighting and at other times when requested.

Sightings of cetaceans and turtles are classified by right angle distance intervals. The intervals used for classification are 0–0.118, >0.118–0.463, >0.463–0.926, >0.926–1.389, >1.389–1.852, and >1.852 km from the plane track. Sightings are classified into right angle distance intervals with the aid of reference marks placed on the blister. The reference marks represent degrees of declination below the visual horizon. The marks are calibrated for an altitude of 229 m.

Only sightings made by the blister observers are used in future analyses and eventual abundance estimation. The aircraft may break from the transect to approach sightings for positive identifications and counts. In the event additional animals are sighted while circling the original sighting, these are included in the total count for the sighting. If the aircraft then breaks to investigate the new sighting and additional sightings are made, the newest sightings are coded as off-transect sightings and are not included in future analysis for abundance estimation.

Survey parameter windows

Sampling was conducted at an altitude of 229 m and at a ground speed of 222 km/hr. Sampling was conducted only in sea states defined by a Beaufort value of 3 or less and with clear visibility of at least 3.7 km. Transects flown under conditions outside the bounds defined for 35% or more of the line were not considered for analysis. Lines flown with greater than 65% of the line within the bounds defined were considered. However, those line lengths outside of the 'sampling parameter windows' were not considered.

SC/Jn81/KW3

Distribution of Killer Whales in the Warm Temperate and Tropical Eastern Pacific

Marilyn E. Dahlheim[1], Stephen Leatherwood[2], and William F. Perrin[3]

ABSTRACT

Records of killer whale occurrence for the warm temperate and tropical eastern Pacific Ocean are summarized from 11 strandings/collections and 581 observations. Levels of sighting effort are identified and used to interpret trends in distribution and movement. Killer whales occur from the Gulf of California more or less continuously along the Pacific Coast from 35°N to just below 5°S. Nearly all records off California and western Baja California were within 150 nm of the coast. North of 20°N, there were only four widely scattered offshore sightings beyond 150 nm. South of 20°N, 56.6% of all sightings were within approximately 300 nm of the coast and 78.4% within 600 nm. Two offshore clusters of sightings occurred, (1) 7° to 14°N, 127° to 139°W and (2) within a band between the equator and 5°N from the Galapagos Islands to 115°W. Herds contained up to 75 animals, with a mean of 5.3 animals per herd. An estimated 91% of the herds contained fewer than 10 animals.

INTRODUCTION

Killer whales, *Orcinus orca,* are cosmopolitan in distribution. There are records of their occurrence from virtually all oceans and major seas and from all ocean zones (for review see Leatherwood and Dahlheim, 1978; Dahlheim, 1981). Concerning their relative abundance by habitat, Mitchell (1975) states that although reported from tropical waters and the open sea, killer whales appear to be most prevalent in the colder waters of both hemispheres, with centers of greatest abundance within 800 km of major continents. Details adequate to support summary statements about the species' distribution and relative abundance, however, have only been reported for four areas: northeast Atlantic (Jonsgård and Lyshoel, 1970); northwest Atlantic (Sergeant and Fisher, 1957); inland marine waters of Washington State, US and British Columbia, Canada in the northeast Pacific (Bigg, MacAskie and Ellis, 1976; Chandler, Goebel and Balcomb, 1977); and coastal Japan (Nishiwaki and Handa, 1958; Kasuya, 1971). Beyond the odd sighting record there is little or no published information currently available on such populations in other regions. This paper reviews the data available from 1907 through 1979 on killer whale occurrence in the eastern Pacific Ocean from latitude 15°S and longitude 160°W, north to latitude 35°N and east to the coastline (Fig. 1).

MATERIALS AND METHODS

Data collection and methods of analysis were the same as those used by Leatherwood, Perrin, Kirby, Hubbs and Dahlheim (1980) for Risso's dolphin, *Grampus griseus*. We reviewed all previously published and unpublished strandings and collections of killer whales in the study area. These data were summarized and their locations plotted and examined for distributional patterns (Fig. 2). All previously published data on sightings of killer whales were reviewed and tabulated.

We examined 306 unpublished observations of free-ranging killer whales from the National Marine Fisheries Service (NMFS) tuna-dolphin observer program (1974–79). An additional 275 unpublished at-sea sightings were available from our files and from the files of other individuals and agencies. We carefully examined these unpublished sighting records for reliability of identification. Interviews with observers and/or the use of photographs assured us of the accuracy of many records. Descriptions of animals with striking black and white coloration, a white oval eye patch, and prominent erect dorsal fin (all diagnostic field characteristics of *Orcinus orca*) aided in verification of the remainder. We discarded questionable records.

catcher boats. The IWC Area where each group of specimens was collected was designated on the data form. The largest sample (n = 177) was collected in Area V. The sample size from Areas III and IV was small (n = 38), and since all the material was collected between 40°E and 90°E, near the dividing line between these Areas, the samples were combined. In addition, it was also indicated whether pods were encountered far into open ice leads or in open water. Details of the numbers of individuals studied by sex and locality of collection are given in Table 2. Since the sample sizes for the longitudinally separate groups for open water were so small they were combined and only the latitudinally separated groups (in ice versus open water) were tested for differences.

Table 2

Orcinus orca sampled for color pattern in Antarctic by Soviet whaling fleets.

	Sex		
Locality	Male	Female	Total*
Area V, 'in ice'	70	65	135
Area V, 'open water'	21	21	42
Area III–IV, 'in ice'	7	7	14
Area III–IV, 'open water'	12	12	24
Total	110	106	216

* 20 samples were from 1977–78 season, 5 from 78–79 and 190 from 79–80 season.

ANALYSIS AND SUMMARY OF RESULTS

General features of *Orcinus* color pattern

In Evans and Yablokov (1978), Guldberg-Nausen's (1894) description of the color pattern of a fetal *Orcinus* was briefly discussed. In their illustration the specimen had all the major components of the *Orcinus* pattern. In addition, their illustrations indicated the presence of a general dorsal cape similar to that described by Perrin (1972) as a general feature of delphinid color patterns. Based on photographic samples from Northern Hemisphere available at the time we considered this was a feature that apparently was not expressed in the adult color pattern. Upon more detailed examination of photographic samples from the Southern Hemisphere several individuals from the area of McMurdo Sound, Antarctic, illustrated a very visible dorsal cape (Fig. 2). The margin of this dorsal cape runs from near the apex of the melon to behind the dorsal fin, passing high over the eye, forming the dorsal margin of the post-ocular patch, and dipping below the dorsal fin to form the lower lateral margin of the post-dorsal fin saddle. On re-examination it was possible to detect this cape in the photographs of all specimens from Antarctic waters and from a few specimens from Argentina. G. M. Vienger (TINRO) also noted that all specimens taken by the Soviet Antarctic fleet had a pronounced cape pattern. This feature is not discernable in photographs of individuals from any of the other geographic areas studied. It is, however, possible with careful scrutiny to detect the margin of a cape in living specimens from Icelandic and Puget Sound waters on display at Sea World, San Diego.

Color pattern component analyses

Because of the previously mentioned differences in our data collection methods, the photographic material and on-site (Soviet Antarctic Whaling Fleet) data were analyzed separately. Depending on the sample size and consistency of the data, some samples from adjoining areas were combined. If the frequency of occurrence of a pattern variant was low for all geographic areas, we dropped the variant out of the analysis. We also assumed that the components of the color pattern varied independently. We would like to caution that in light of the observed connection (dorsal cape) between the post-dorsal fin saddle and post-ocular patch this assumption of independence may not be valid for these two components.

To test for homogeneity among variants of each color pattern component as a function of geographic area Chi-square (χ^2) contingency tests were performed (Sokal and Rohlf, 1969). In 2 × 2 contingency tables where cell size was less than 5, Yates correction was used. All analysis was performed using SPSS (Statistics Package for the Social Sciences, Nie *et al.*, 1975).

Photographic data

All photographic material was segregated by geographic region (see Table 1). Material was pooled from all pods observed within these regions. Due to the gross level of the analysis, no attempt was made to control for interpod differences. Tracings were made of each visible component. These tracings were used to determine which variant of each component (Fig. 1) provided the best match. The frequency of occurrence of component variants for each geographic area was tabularized for comparison.

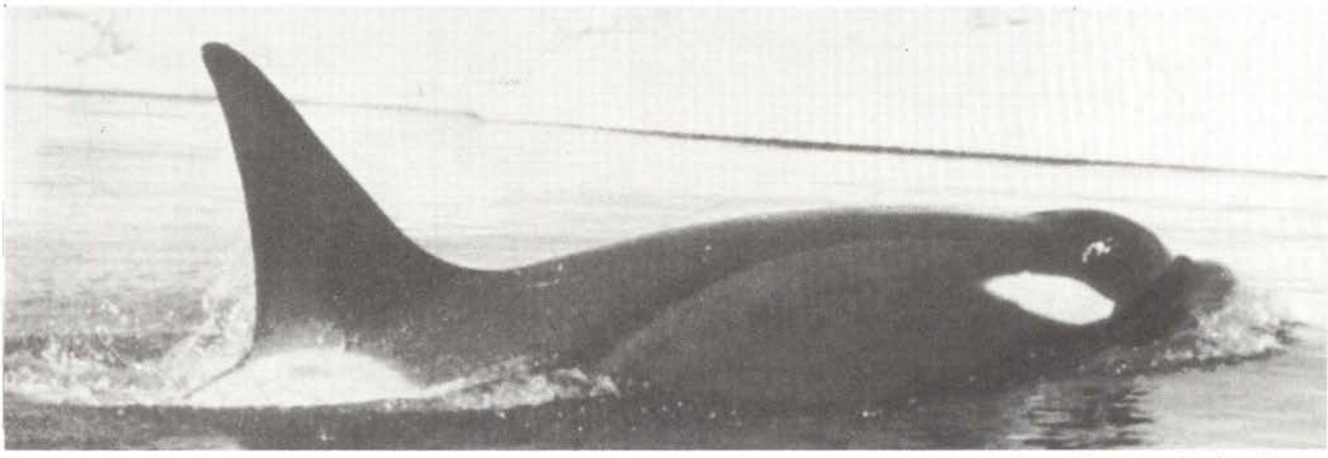

Fig. 2. Expression of dorsal cape pattern was observed in all Antarctic *Orcinus orca* studied. This photo illustrates the dorsal cape configuration of the McMurdo Sound group.

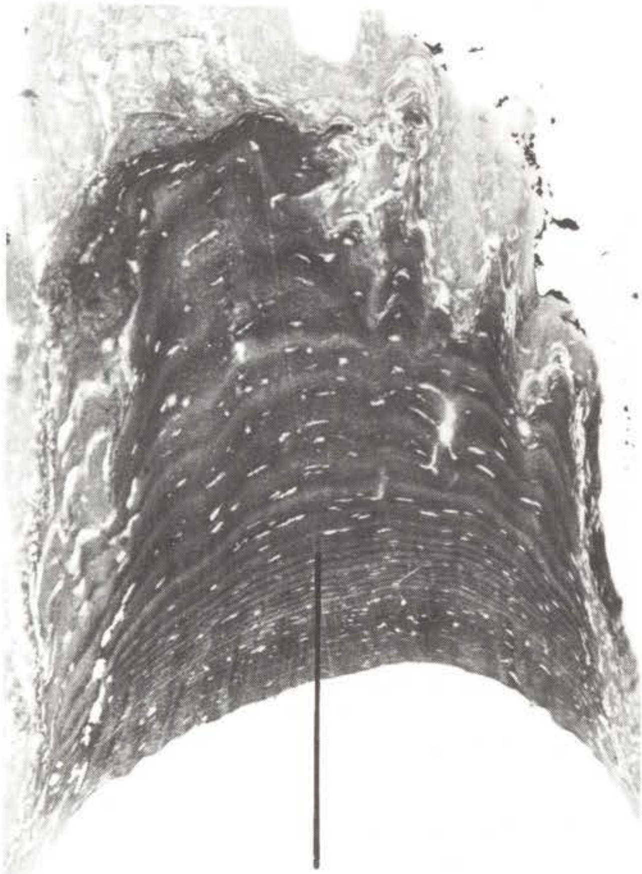

Fig. 9. Stained section of minke whale ear plug. Line indicates transition phase.

There seems a correlation between maturity and the presence of a transition phase in minke whales at Durban, although there is insufficient material to test for each sex separately (Table 21). The assumption has therefore been made that the transition phase also represents the attainment of sexual maturity in minke whales.

Table 21

Presence of a transition phase in the ear plug of minke whales from Durban

Sexual maturity classification	Number examined	% showing transition phase
Immature	21	4.8
Pubertal[1]	12	16.7
Mature	94	83.0

[1] One to two corpora in ovaries or both mature and immature tubules in testes.

The particular value of the transition phase is that it is possible to investigate not only the current age at sexual maturity but also historical trends in this parameter (Lockyer, 1979; Masaki, 1976, 1979). However most previous such analyses have plotted the age at which the transition phase appears against the year of birth of the whale. This approach leads to a bias (which has been recognised by most authors) in that in more recent years there is under-representation of late-maturing whales, leading to under-estimation of the mean age at sexual maturity in those year classes (Free and Beddington, 1980; Horwood, 1980).

In this paper the data for 112 animals have been plotted two ways, firstly against the year of birth and secondly against the year in which the whale became sexually mature (Fig. 10).

Because of the small amount of material available, data for both sexes have had to be combined, but as male and female minke whales mature at very similar ages (Masaki, 1979) the results should be applicable to either sex.

Both data sets indicate a decline in the age at sexual maturity (= transition phase) over time. Ignoring the two oldest animals (whose inclusion might unduly weight the results), linear regressions have been fitted to the remaining data, producing the following estimating equations:

$$y = 11.58 - 0.0986x \text{ (year of maturation)}$$
$$y = 13.21 - 0.1535x \text{ (year of birth)},$$

where y = age at sexual maturity
x = year of maturation or birth (1935 = 1 and 1925 = 1, respectively)

The slopes of both regressions are significantly different from zero ($t = 3.38$, $p. < 0.005$; $t = 6.85$, $p < 0.001$, respectively), though that for the year of birth seems to be somewhat greater than that for the year of maturation. However (as noted above), the fact that late-maturing animals in the more recent age classes have not yet matured means that the coefficient of slope for year of birth may be overestimated. This bias probably came into effect from the 1957 year class, as animals born in that year and maturing at age 12 would only reach maturity in 1969 (or after the sampling started). A linear regression fitted to the data prior to 1957 yields an estimating equation of

$$y = 12.04 - 0.0999x,$$

which is very close to that for the year of maturation. Hence Fig. 10 may be free of the bias inherent in plots of age at maturity against year of birth. From that regression the age at maturity of animals reaching maturity is estimated to have declined from 10.5 in 1945 to 7.7 in 1973 (s.e. ± 1.9 years).

The latter estimate is within the ranges predicted from direct biological observations for both sexes off Durban during the period 1970–75 (in which most of the material was collected). However the two sets of results are not directly comparable, as they concern different segments of the population.

A decline in the age at sexual maturity for both sexes of southern minke whales has also been described by Masaki (1979), although the decline was much greater, from an average of 13.8 years prior to the 1944 year class to 6.2 years after the 1965 year class. Some of this discrepancy may be due to the different methods of analysis used.

This decline commences well before concerted pelagic exploitation of southern minke whales began (1971/72), and may reflect a faster growth rate due presumably to more food being available as a result of depletion of other baleen whale species feeding on *Euphausia superba* (IWC, 1979).
